(54) **Method of fabrication of an infrared radiation detector and more particularly an infrared sensitive bolometer**

(57) A method of fabricating an infrared sensitive bolometer, comprising the steps of:

- forming a sacrificial layer (11, 12 or 43) on a substrate (10 or 41);
- patterning said sacrificial layer (11, 12 or 43);

- depositing or growing a layer (13 or 42) consisting essentially of polycrystalline SiGe on said sacrificial layer;
- depositing an infrared absorber (49) on said polycrystalline SiGe layer;
- removing the sacrificial layer (11, 12 or 43).

FIG. 1b

EP 0 867 702 A2

Description**Object of the Invention**

5 The present invention is related to a method of fabrication for an infrared radiation detector, and more particularly an infrared sensitive bolometer, using micro-machining techniques.

The present invention is also related to the infrared detector itself.

Finally, the present invention is related to a specific use of surface micro-machining techniques.

Background of the invention

10 A large number of infrared detection methods exist, each being based on a different working principle. Infrared detectors are being used in a large number of applications.

15 The present invention focuses on the group of detectors where the energy of the absorbed infrared radiation raises the temperature of the detecting element thereby changing its electrical conductivity. These detectors, known as bolometers, are fabricated from different materials like metals, permalloy, vanadium oxide, or (poly-crystalline) silicon.

In order to obtain a high performance, two points are of paramount importance:

20 1°) the total thermal conductance G from the resistor to the substrate, must be low, so as to maximise the temperature increase for a given amount of energy deposited on the detector;

2°) the absolute value of the temperature coefficient of resistance (TCR) α (i.e. the percent variation of the device resistance for a temperature increase of 1 K) must be large.

25 The first point is related to the geometrical structure of the detector and to the thermal properties of the material (s) forming it, and the second one is related only to the electrical properties of the active material.

30 With technologies suggested in the state of the art of micro-machining good thermal insulation is obtained in two different ways either by micro-machining an electrically and thermally insulating membrane and depositing the active material onto it, either by micro-machining structures suspended over the substrate directly using the active material. This last approach is more simple and straightforward but requires an active material with low thermal conductance and with mechanical properties adequate for micro-machining. Until now, this is applied only to poly-crystalline silicon (poly-Si) bolometers.

35 As example of the first approach is reported in document WO-A-9313561 which describes a method for fabricating an integrated infrared sensitive bolometer having a polycrystalline element whereby an oxide region deposited on silicon nitride covered with a first polysilicon layer which is etched to provide a location for a bolometer element. A second polysilicon layer is deposited and doped to achieve a desired temperature coefficient of resistivity of 1 to 2%/°C. The second polysilicon layer forms an infrared sensitive element over the oxide region. Openings are etched in the infrared sensitive element to permit an etchant to remove the oxide region resulting in the sensitive element being suspended over the cavity. The thermal conductance is determined by the thermal conductivity of poly-Si and by the shape of the etch of the first poly-Si layer.

40 An example of the second approach is described in the document "Infrared Focal Plane Array Incorporating Silicon IC Process Compatible Bolometer" of Tanaka, et al published in IEEE Transactions on Electron Devices, Vol. 43, No. 11, November 1996 which describes a 128 x 128 element bolometer infrared image sensor using thin film titanium. The device is a monolithically integrated structure with a titanium bolometer detector located over a CMOS circuit that reads out the bolometer's signals. By employing a metallic material like titanium and refining the CMOS readout circuit, it is possible to minimize 1/f noise. Since the fabrication process is silicon-process compatible, costs can be kept low.

45 The article "The Growth and Properties of Semiconductor Bolometers for Infrared Detection" of M.H. Uniwisse, et al in SPIE Vol. 2554/43 describes how to develop bolometer arrays from semiconductor materials, such as the amorphous and microcrystalline phases of Si, Ge, and SiGe. In this work, the use of amorphous and microcrystalline SiGe: H is suggested in order to reduce the large 1/f noise and the large resistivity of amorphous silicon. No use of the thermal properties of SiGe is mentioned.

50 The article "Thin Film Boron Doped Polycrystalline Silicon Germanium for the Thermopiles" of P. Van Gerwen, et al in the 8th International Conference on Solid-State Sensors and Actuators, and Eurosensors IX, Stockholm, Sweden, June 25-29, 1995 describes the use of polycrystalline silicon-germanium for thermopiles instead of polysilicon. Thermopiles can be used for infrared detection if incident infrared is absorbed by an absorption layer near one junction which will heat up. The other junction is put on a heat sink, which will not heat. The temperature difference between the two junctions creates a voltage related to the absorbed infrared. These thermopiles are fabricated according to bulk micro-machining techniques.

Double-sided processing and special handling requirements though make bulk micro-machining incompatible with

standard IC fabrication techniques.

Document US-A-5367167 is describing a bolometer for detecting radiation in a spectral range including an integrated circuit substrate and a pixel body spaced from the substrate. The pixel body comprises an absorber material such as titanium for absorbing radiation in the spectral range. In addition, a variable resistor material which is the active element made of amorphous silicon is formed over an insulating layer.

The article "Thermal stability of Si/Si_{1-x}Ge_x/Si heterostructures deposited by very low pressure chemical vapor deposition" published in Applied Physics Letter, vol. 61, No. 3, of 20 July 1992, pp. 315-316 is describing structures using crystalline SiGe deposited on crystalline Si. More particularly, this document is related to the study of the thermal stability of metastable Si/Si_{1-x}Ge_x/Si strained structures deposited by very low pressure chemical vapor deposition.

Aims of the invention

The first aim of the present invention is to provide a method of fabricating an infrared radiation detector, and more particularly an infrared sensitive bolometer, having improved thermal insulation.

A second aim of the present invention is to suggest a method of fabricating a bolometer which can be arranged in arrays of pixels for applications such as (night) cameras, for instance.

A third aim of the present invention is to disclose the fabrication of an infrared radiation detector with a material having lower thermal conductance compared to state of the art detectors but still compatible with standard IC technologies and having electrical and mechanical properties which are at least similar to those of the state of the art.

Main characteristics of the present invention

As a first aspect, the present invention is related to a method of fabricating an infrared sensitive bolometer comprising the steps:

- forming a sacrificial layer on a substrate;
- patterning said sacrificial layer ;
- depositing or growing an active layer made of polycrystalline SiGe on said sacrificial layer;
- depositing an infrared absorber on said polycrystalline SiGe layer;
- removing the sacrificial layer.

Preferably, the method further comprises, after depositing or growing an active layer, the steps of:

- patterning said polycrystalline SiGe layer, thereby forming an active area and supports of the detector;
- performing a high doping of the supports and a moderate doping of the active area;
- depositing an infrared absorber on said polycrystalline SiGe layer.

In this way, a poly-SiGe resistor thermally insulated from the substrate will be formed. Infrared radiation will generate an increase of temperature which will in turn originate a decrease in resistance.

The sacrificial layer can be defined as a layer used only in order to realize the purpose of thermal insulation of the bolometer. In fact, the bolometer should be thermally insulated, otherwise, its temperature will be no longer controlled by the incident radiation. Thus, the structure is built on the top of the sacrificial layer and is connected to the substrate through the supports. After removing the sacrificial layer, the supports will be the thermal path between the device and the substrate. Hence, the thermal conductance of the supports play an important role in insulating the device and therefore should be minimized.

The active area can be understood as the area of the bolometer, which works as a detector portion.

Patterning should be understood as forming structures on/in different layers on/in the substrate according to the techniques known in the microelectronics and micromachining such as photolithography.

Preferably, the step of patterning said sacrificial layer comprises the steps of defining anchor points.

Furthermore, the method of fabrication according to the present invention can also include the step of depositing one or more intermediate layer(s) in said substrate prior to depositing said sacrificial layer and wherein the intermediate layer(s) comprise at least an etch stop layer.

Preferably, the substrate is a Si substrate and the active layer is made of polycrystalline Si_{70%} Ge_{30%}.

According to one preferred embodiment, the regions having the sacrificial layer can be formed with a porous silicon region.

According to another preferred embodiment, these regions having the sacrificial layer can be created by depositing and patterning an insulating layer made of an oxide.

The steps of high doping of the supports and moderate doping of the active area can be achieved by means ion

implantation.

The polycrystalline SiGe layer is preferably deposited by chemical vapour deposition at atmospheric pressure or at a reduced pressure.

The infrared absorber can be created according to a first preferred embodiment with a stack of layers comprising a metallic layer, an insulating layer and a semi-transparent metallic layer. According to a second embodiment, the infrared absorber only comprises a metallic layer and an insulator of appropriate thickness.

According to a third preferred embodiment, the infrared absorber comprises at least a semitransparent metallic layer

As a second object, the present invention is related to a method of controlling stress in a polycrystalline SiGe layer deposited on a substrate such as a silicon oxide substrate by varying the deposition pressure and/or the annealing temperature.

Brief description of the drawings

- Figures 1a and 1b represent the cross-section of two possible embodiments of structures for a bolometer achieved by the method of the present invention while figure 1c represents the top view of both embodiments shown in figures 1a and 1b.
- Figure 2 shows a schematic representation of a pixel and its external electronics of a camera according to one embodiment of the invention.
- Figure 3 represents the behaviour of stress of a polycrystalline SiGe film deposited on a carrier as a function of the annealing temperature for two different deposition pressures.
- Figure 4 represents the dependence of the power dissipated in a structure similar to the structure described in Figure 1C on the temperature rise of the bolometer. The slope of the curve gives the thermal conductance ($W/\Delta T$) of the bolometer, wherein the dots refer to a structure using poly-Si as active material while the small squares refers to a structure using poly-SiGe as active material according to the invention.
- Figs. 5a to 5f represent the side view and the top view for several steps of the fabrication process of a bolometer according to a preferred embodiment of the present invention.
- Figs. 6a & 6b show SEM pictures of two micromachined bolometers according to several embodiments of the invention having lateral dimensions of 50 μ m(a) and 25 μ m(b) respectively and wherein the thickness of the poly SiGe layer is 1 μ m, the width of the supports is 5 μ m and 0.6 μ m for the 50x50 μ m(a) bolometer(s) and the 25x25 μ m(b) bolometer respectively.
- Figure 7 displays the experimentally measured absorbance of an infrared absorber used in one embodiment of the invention, versus the wavelength of the radiation.
- Figure 8 represents the experimentally measured responsivity \mathfrak{R} as a function of the supply voltage of a bolometer fabricated according to the invention and wherein the responsivity is expressed in Volt/Watt and represents the voltage generated per unit of power incident in the bolometer.
- Figure 9 displays the measured frequency dependence of the total noise of a bolometer according to one embodiment of the invention as shown in figure 6b over the range extending from 1 Hz to 100 KHz.

Detailed description of the present invention

In an aspect of the present invention, a method of fabricating an infrared bolometer is described, which has an improved thermal insulation behaviour. Furthermore, a bolometer fabricated according to the method of the invention is described.

In order to evaluate a material for the realisation of a bolometer, it is necessary to understand how its properties influence the responsivity and the noise of the bolometer itself.

According to the invention, use is made of an alloy comprising polycrystalline Silicon Germanium (poly-SiGe).

This material has lower thermal conductance than polycrystalline silicon, and is compatible with the standard IC technology. It also has electrical and mechanical properties which are superior to those of polycrystalline silicon.

Several possible structures of bolometers are shown in the figures 1a, 1b, and 1c.

Figure 1a represents a bolometer wherein porous silicon regions 11 have been formed on a substrate 10, while figure 1b represents the deposition and the patterning of an insulating layer 12 on a substrate 10. In both cases, a polycrystalline SiGe layer 13 is then deposited and patterned in order to form the active area 16 and the supports 15 connected to the substrate at the anchor points 14 as represented in figure 1c.

It is obvious that the particular shape of figure 1c has to be considered only as an example and that the present invention is not limited to this particular shape, but covers all similar structures, characterised by long and thin supports.

For the purpose of teaching of the invention, an important application of bolometers of the invention is described below. One of the most important applications of the bolometers is the realisation of an infrared camera. Said camera is an array of pixels, each containing a bolometer and some electronics.

A schematic view of a pixel is shown in figure 2. The bolometer is represented by the reference 21, and is connected to a CMOS switch 22, built in the substrate, while the signal and gate lines 23 and 24 go to the external read-out. Externally to the array, a voltage waveform generator 25 and a load resistor 26 are provided. During calibration, the CMOS switch 22 is closed, a short voltage pulse is sent to the bolometer, and the voltage drop across the load resistance is measured. This operation is repeated in presence of infrared radiation. A signal is defined as the difference of the voltage across the load resistor measured with and without infrared radiation. Note that in a normal operation, the duration of the voltage pulse is shorter than the thermal time constant of the bolometer, and does not create a temperature increase.

The volt responsivity \mathfrak{R} , i.e. the signal per unit incident power of a bolometer is given by:

$$\mathfrak{R} = \frac{|\alpha| \eta V R_L R_B}{(R_L + R_B)^2 G}$$

where R_L and R_B are the load resistance and bolometer resistance, respectively.

G is the thermal conductance of the supports towards the substrate. It depends mainly on the thermal conductivity of the material and the geometry of the supports.

An appropriate expression of the thermal conductance (for long supports) is

$$G = g \frac{wt}{l}$$

where the w , t and l are the width, the thickness, and the length of the supports respectively. It is clear from the above expression that the thermal conductance can be minimized by using thin and long supports.

It is also evident that in order to obtain a large responsivity, the applied voltage V , the absolute value of the temperature coefficient of resistance α and the infrared emissivity η must be large, while the total thermal conductance toward the support, G , must be minimised.

The noise which affects this responsivity signal has two contributions: external (from read-out electronics, load resistor, amplifiers...) and internal (due to the bolometer itself). External noise can be reduced by design optimisation and is to a good extent independent of the bolometer characteristics. Concerning the bolometer noise, the relevant quantity is not the noise itself but the noise equivalent power (NEP), i.e. the power which generates a signal equal to the noise.

Three contributions should be considered to the noise equivalent power: the Johnson noise, the temperature fluctuation noise and the low frequency noise typical of the active material.

For the case of Johnson noise, it can be defined as :

$$NEP_J = \frac{\sqrt{4 K T R_B}}{\mathfrak{R}} \Delta f$$

It can be minimised by reducing the bandwidth Δf with appropriate actions on the electronics or by using a low value for the bolometer resistance.

For the case of thermal fluctuation noise, it can be defined as : $NEP_{th} = \sqrt{4kGT^2} \Delta f$, wherein Δf is a thermal bandwidth of the order of the inverse of the thermal time constant of the bolometer.

The $1/f$ noise is given by

$$V_{n,1/f} = kV_b \sqrt{\frac{\rho}{WLTf}}$$

wherein the coefficient k depends of the microcrystalline structure of the material, V_b is the voltage across the terminals of the bolometer, ρ is the resistivity, W , L and T are the width, length and thickness of the pixel respectively. It should be noted that also this contribution to the noise is, as the Johnson one, minimized by using low values of the bolometer resistance. Furthermore, the $1/f$ noise increases proportionally with the biasing voltage which is not the case for the Johnson noise.

It is evident that the conditions which maximise the responsivity also minimise the NEP. In particular, as far as the material properties are concerned, one needs low G and large αI . These properties for the poly-SiGe used in the present invention will be discussed further.

Meanwhile, the influence of $1/f$ noise will be discussed together with the responsivity results.

Thermal conductance and stress properties of the material used in the bolometer of the invention

The possibility of realising a good thermal insulation depends on the geometry of the structure and on the thermal conductance of the material. It is well known that in order to realise micro-machined structures similar to that of figure 1 it is important to use films with low, and possibly tensile, internal stress.

In figure 3, the behaviour of the stress in a poly-SiGe film having a thickness of 1.0 μm deposited onto an oxide is shown as a function of the annealing temperature.

The material grown at atmospheric pressure **32** has a relatively low compressive stress, and this stress is reduced to zero after an annealing at 900 °C for 30 minutes. For comparison, poly-Si grown by low pressure chemical vapour deposition at 620 °C exhibits an internal compressive stress larger than 300 MPa, which is annealed out at a temperature of 1050°C.

The material grown at reduced pressure **31** (lower than the atmospheric pressure e.g. 40 torrs) has a tensile internal stress, which is almost insensitive to annealing. The above observations indicate that the internal stress of poly-SiGe can be tuned by appropriate choice of growth/deposition conditions and annealing temperatures. This allows to choose the stress of the active layer so as to compensate the one of the layers forming the infrared absorber. By this procedure, low stress and mechanically stable structures can thus be obtained. Except that in the case of an infrared absorber with very low tensile stress, this compensation procedure requires low annealing temperature or even no annealing at all.

Furthermore, the thermal conductivity of poly-SiGe depends on the concentration of germanium atoms and has a minimum at a germanium concentration of 30%. In Figure 4, the temperature increase ΔT obtained by dissipating the power W in a structure similar to that of Figure 1C is reported. The dots refer to a structure made in poly-Si, the squares to a structure made of poly SiGe. The two structures are identical in shape but the thermal insulation is almost 6 times larger for poly SiGe. Using a finite element model for thermal conductivity, the values 17 W/mK and 2.5 W/mK are deduced for the thermal conductivity of the two materials. This reduction of thermal conductivity has obvious beneficial effects on the responsivity and on the noise equivalent power of the bolometer.

Electrical properties of the materials used in the bolometer of the invention

In order to use a material for realising a bolometer, it is necessary to control by appropriate doping, both its conductivity and the dependence of conductivity on temperature. In Table I, the conductivity and the temperature coefficient of resistance are reported for different implanted doses of boron. The annealing temperature after ion implantation is also indicated.

It is possible to note that at low and medium doses, the temperature coefficient of resistance is large, as necessary for a well performing bolometer. The resistivity of highly doped material is very low. This allows to regard the highly doped supports as conducting leads. The attention is pointed to the fact that activation of dopants is obtained also at temperatures as low as 650°C. This implies that a low thermal budget process is possible.

In conclusion, it can be stated that these properties show that poly-SiGe is a suitable material for surface micro-machining applications.

Detailed description of an example according to a preferred embodiment of the present invention

In the following, the description is focused to the case of a sacrificial layer realised with an oxide, as represented in figure 1b. An example of thermal oxide can be TEOS. The process described hereafter applies with minor modification to a sacrificial layer made of porous silicon as represented in figure 1a.

The substrate is a silicon wafer, said substrate being already processed in order to form the appropriate CMOS switches of the infrared camera and covered with standard passivation layers.

In the following, the realisation of the bolometer is explained and no details will be given about the connection of the bolometer to the underlying electronics and to the external circuitry as they are not relevant to the present invention

and can be made according to the knowledge of the man skilled in the art.

It is important to note at this stage that the preparation of bolometers using an already processed substrate is made possible by the relatively low temperature at which the bolometer is prepared.

As shown in Fig. 5a, a thin layer **42** (e.g. 100 nm thick) is deposited onto the substrate **41**, in order to serve as etch stop during the etching of the sacrificial layer **43**. This layer **42** can be according to a first preferred embodiment a silicon-rich silicon nitride or any other material which is resistant to the etching agent of the sacrificial layer. According to another preferred embodiment, the thin layer **42** can be an undoped poly-Si layer.

The sacrificial layer **43** (1 or 2 μm of TEOS) is then deposited and patterned by standard lithography. Typical lateral dimension of the remaining TEOS regions after patterning vary from 20 μm to 50 μm .

Subsequently, as represented in figure 5b, a poly-SiGe active layer **44** (0.5 μm or 0.3 μm thick) is deposited in a chemical vapour deposition system at a temperature comprised between 600°C - 700°C and preferably around 650°C at atmospheric or at reduced pressure.

Gases used for the deposition are diclorosilane and germane. Their relative proportion is chosen in such a way that the concentration of germanium in the film is about 30%. This is the concentration which minimises the thermal conductivity.

Using the above process gas, the nucleation of poly-SiGe on oxides is slow, then a thin (30Å) nucleation layer of poly-Si is used. It is also possible to use a mixture of silane and germane. In this case, no nucleation layer will be necessary.

After the poly-SiGe deposition, a thin layer of silicon nitride **45** is deposited. It will serve for electrical insulation of the absorber from the active element.

The stack of these two layers is then patterned. The holes **46** on the active layer will be useful during the sacrificial layer etching. The contacts **47** drawn in figure 4b are large and useful for testing single devices. When the device is inserted in a matrix their dimension can be reduced.

In figure 5c is shown that the contacts **47** and the supports **48** are implanted with a high boron dose and the active area with a moderate dose. Instead of implanting the active area by a low doping dose, it is also possible to dope it at a desired level during the deposition of poly-SiGe by adding appropriate gases to diclorosilane and germane. An annealing for dopant activation and diffusion is performed. By means of the above dopings, the supports act as electrical contacts and the conductivity and the TCR of the active area is tuned to the desired value.

The construction of the bolometer proceeds by the deposition and patterning of the absorber **49** as represented in figure 5d. At this stage, either vias to the underlying electronics are opened or metal contact **410** are deposited for test purposes (see figure 5e).

The construction of the bolometer is completed by the removal of the sacrificial layer using standard micro machining techniques (see figure 5f). The absorber can be composed, for example, of a triple layer: starting from the silicon nitride, a metal reflector, an insulating layer about 1.5 μm thick, and a semitransparent metal are formed. Other possibilities for preparing the absorber exists and can be used.

Another absorber can be made as follows: an infrared absorber having a Ti layer of 0.2 μm thick, a polyimide (Hitachi polyimide) layer of 1.4 μm thick and a semitransparent NiCr layer having a thickness of 5 nm is suggested.

The Ti layer can be up to 1 μm thick in order to have better reflector properties. However, if the thickness of this Ti layer is too large, the stress will also be too high and the device will crack.

The thickness of the polyimide define the wavelength maximal absorption. This means that if the thickness changes, the wavelength will also change.

The formula $T = \frac{\lambda}{4n}$ is determining, wherein according to this example, $\lambda = 10 \mu\text{m}$ and $n = 1.8$ which will give a thickness of 1.4 μm .

The NiCr layer can have a thickness of 2 to 5 or 10 nm or even more. For instance, for $\lambda = 10 \mu\text{m}$, a thickness of 5 nm will give 100% absorbance which corresponds to the conditions for destructive interference.

In figure 6, SEM pictures of two micromachined bolometers are represented. These bolometers have lateral dimensions of 50 μm and 25 μm respectively with a thickness of the poly SiGe layer of 1 μm . For the small devices, the support width is only 0.6 μm , and the thermal conductance in vacuum is only 10^{-7} W/K.

In figure 7, the absorbance of the infrared absorber as a function of the wavelength is represented, it is shown that an absorbance of 0.7 can be obtained in the 8-14 μm region.

In Figure 8, the responsivity measured as a function of the applied dc bias voltage is reported. Considering that in camera operation, pulsed bias is used, and the voltage can be increased up to 5 V, responsivities in excess of 10^5 V/W can be obtained.

In Figure 9, the bolometer noise as a function of frequency is reported. A frequency independent detectivity cannot be defined. Having in mind infrared camera application, considering a frequency bandwidth extending from 10 to 100000 Hz, the average noise and detectivity in this range can be computed.

Claims

1. A method of fabricating an infrared sensitive bolometer, comprising the steps of:
 - forming a sacrificial layer (11, 12 or 43) on a substrate (10 or 41);
 - patterning said sacrificial layer (11, 12 or 43);
 - depositing or growing a layer (13 or 42) consisting essentially of polycrystalline SiGe on said sacrificial layer;
 - depositing an infrared absorber (49) on said polycrystalline SiGe layer;
 - removing the sacrificial layer (11, 12 or 43).
2. The method as recited in claim 1, further comprising, after depositing or growing said active layer (14 or 42), the steps of:
 - patterning said polycrystalline SiGe layer (13 or 42), thereby forming an active area (16 or 47) and supports (15 or 48) of the active area;
 - performing a high doping of the supports (15 or 48) and a moderate doping of the active area (16 or 47).
3. The method as recited in claim 1 or 2, wherein said step of patterning the sacrificial layer comprises the step of defining anchor points (14).
4. The method as recited in any one of the preceding claims, further comprising the step of:
 - depositing one or more intermediate layers on said substrate prior to depositing said sacrificial layer (11, 12, 43).
5. The method as recited in claim 4, wherein the intermediate layer(s) comprise(s) at least an etch stop layer.
6. The method as recited in any one of the preceding claims, wherein the substrate is a Si substrate.
7. The method as recited in any one of the preceding claims, wherein the sacrificial layer comprises porous silicon.
8. The method as recited in any one of the preceding claims 1 to 6, wherein the sacrificial layer is formed with the deposition and the patterning of an insulating layer made of an oxide.
9. The method as recited in any one of the preceding claims, wherein the active layer (13 or 42) is made of polycrystalline $\text{Si}_{70\%}\text{Ge}_{30\%}$.
10. The method as recited in claim 9, wherein the active layer (13 or 42) is deposited by chemical vapor deposition.
11. The method as recited in claim 9, wherein the active layer (13 or 14) is deposited at atmospheric or reduced pressure.
12. The method as recited in any one of the preceding claims, wherein the infrared absorber (49) is obtained by depositing at least a semitransparent metallic layer

13. The method as recited in any one of the preceding claims 1 to 11, wherein the infrared absorber (49) is obtained by depositing at least a metallic layer and an insulating layer.
- 5 14. The method as recited in any one of the preceding claims 1 to 11, wherein the infrared absorber (49) is obtained by depositing at least a metallic layer and an insulating layer and a semitransparent metallic layer.
15. Infrared sensitive bolometer, comprising an active area (16 or 47) and an infrared absorber (49), wherein said active area comprises a polycrystalline SiGe layer, and is suspended above a substrate.
- 10 16. Infrared sensitive bolometer as recited in claim 15, wherein a thin layer of silicon nitride (45) is located between the polycrystalline SiGe layer (44) and the infrared absorber (49).
17. Infrared sensitive bolometer as recited in claims 15 or 16, wherein the infrared absorber (49) comprises at least a semitransparent metallic layer.
- 15 18. Infrared sensitive bolometer as recited in claim 15 or 16, wherein the infrared absorber (49) comprises a metallic layer and an insulating layer.
19. Infrared sensitive bolometer as recited in claim 15 or 16, wherein the infrared absorber (49) comprises at least a metallic reflector an insulating layer and an semitransparent metallic layer.
- 20 20. An infrared camera comprising an array of pixels, each of them containing a bolometer as recited in any one of the preceding claims 15-19 and readout means.
- 25 21. A method of controlling the stress in a polycrystalline SiGe layer deposited on a substrate by varying the deposition pressure.
22. The method of controlling the stress as recited in claim 21, wherein the substrate is a silicon oxide substrate.
- 30 23. The method of controlling the stress as recited in claim 21 or 22, further comprising the step of annealing said layer.
24. The method of controlling the stress as recited in any one of the preceding claims 21-23, wherein said SiGe layer is deposited at reduced pressure.
